22 **ABSTRACT**

23 Conservation of species under climate change relies on accurate predictions of species ranges

24 under current and future climate conditions. To date, modelling studies have focused

25 primarily on how changes in long-term averaged climate conditions are likely to influence

26 species distributions with much less attention paid to the potential effect of extreme events

27 such as droughts and heatwaves which are expected to increase in frequency over coming

28 decades. In this study we explore the benefits of tailoring predictor variables to the specific

29 physiological constraints of species, or groups of species. We show how utilizing spatial

30 predictors of extreme temperature and water availability (heat-waves and droughts), derived

31 from high-temporal resolution, long-term weather records, provides categorically different

32 predictions about the future (2070) distribution of suitable environments for 188 mammal

33 species across different biomes (from arid zones to tropical environments) covering the whole

34 of continental Australia. Models based on long-term averages-only and extreme conditions-

35 only showed similarly high predictive performance tested by hold-out cross-validation on

36 current data, and yet some predicted dramatically different future geographic ranges for the

37 same species under 2070 climate scenarios. Our results highlight the importance of

38 accounting for extreme conditions/events by identifying areas in the landscape where species

39 may cope with average conditions, but cannot persist under extreme conditions known or

40 predicted to occur there. Our approach provides an important step toward identifying the

41 location of climate change refuges and danger zones that goes beyond the current standard of

42 extrapolating long-term climate averages.

43

INTRODUCTION

There is strong evidence that climate change is already influencing natural systems (Parmesan 2006), and an increasing number of species are projected to be at risk of extinction unless effective mitigation and conservation actions can be implemented (Thomas et al. 2004). Accurate predictions of species responses to projected changes in climate could greatly enhance the effectiveness of conservation actions (Guisan et al. 2013). This need, along with advances in species distribution modelling techniques (SDMs), has led to a proliferation of studies examining changes in species distributions linked to recent climate change (Chen et al. 2011, VanDerWal et al. 2012a), as well as predictions of future distributions of taxa across broad geographic scales (Peterson et al. 2002, Thuiller et al. 2005).

To date, modelling studies have focused primarily on how changes in mean temperatures and rainfall are likely to influence species distributions (Porfirio et al. 2014), with less attention paid to the effect of extreme events such as droughts, cyclons and heatwaves, on species persistence. The frequency and severity of extreme weather events such as heatwaves are predicted to increase (IPCC 2014). These extreme conditions can play an important role in regulating population dynamics and thus constrain species distributions (Harrison 2000, Frederiksen et al. 2008, Wernberg et al. 2013), either directly, via thermal stress, or indirectly, by influencing food or habitat availability or disturbance processes such as fire (Andersen et al. 2012, Bateman et al. 2012, Cadenhead et al. 2016). For example, population declines, range contractions and local extinctions of birds and mammals have been reported or predicted in relation to thermal stresses caused by very hot temperatures coupled with drought conditions (Welbergen et al. 2008, McKechnie and Wolf 2010, Krockenberger et al. 2012). In contrast, extreme heavy rainfall events that drive lush vegetation growth are

68   associated with booms of rodent populations in arid and semi-arid zones of Australia and

69   America (Parmesan et al. 2000, Holmgren et al. 2006, Letnic and Dickman 2006, Greenville

70   et al. 2012) .

71   Mechanistic and process-based niche models represent valuable tools that can be used to

72   predict population trends and geographic distributions of species in relation to these direct

73   and indirect impacts of climatic conditions by explicitly accounting for demographic

74   processes and/or physiological tolerances of the target species, as well as daily or yearly

75   variation in weather (Anderson et al. 2009, Kearney and Porter 2009, Briscoe et al. 2016).

76   However process-based models are typically data-hungry, and for most species in most

77   ecosystems in most areas of the world there exists insufficient data, knowledge, expertise and

78   computational resources to fit mechanistic models to a large enough portion of the biota such

79   that they could be widely used for comprehensive conservation planning or ecological impact

80   assessment of climate change (Kearney et al. 2010, Dormann et al. 2012, Peterson et al.

81   2016). Despite their many shortcomings (Dormann 2007, Jackson et al. 2009, Jarnevich et al.

82   2015), correlative species distribution models will, for the foreseeable future, remain the most

83   widely used tools to forecast the effects of climate change on biodiversity (Thomas et al.

84   2004, Thuiller 2007, Franklin 2010, Dormann et al. 2012).

85   Correlative SDMs relate species' occurrence data to spatial variation in environmental

86   conditions (Franklin 2010). These can be used as a good approximation to process-based

87   models to forecast species distributions under climate change, if the environmental predictors

88   selected for fitting the models are known to directly influence population persistence of the

89   target species (Kearney et al. 2010). While the use of ecologically and biologically

90   meaningful variables in correlative SDMs is widely advocated in the SDM literature (Guisan

91   and Zimmermann 2000, Araújo and Guisan 2006, Elith and Leathwick 2009, Jarnevich et al.

92   2015), most of the studies forecasting future distribution ranges still rely primarily on the use

4

of long-term average climatic variables (e.g. bioclim variables; Milanovich et al. 2010,

Franklin et al. 2013). Recently, biogeographic studies have started to implement predictors

accounting for variability and stochasticity of weather for making inferences about current

species distribution ranges/patterns (Zimmermann et al. 2009, Reside et al. 2010, Bateman et

al. 2012, Seabrook et al. 2014, Briscoe et al. 2016). Studies that have explored the influence

of extreme weather conditions on future species distributions (e.g. Porfirio et al. 2014,

Briscoe et al. 2016) have focused on few species or a small geographic extent, limiting

generalization to other species or environments.

Australian mammals present an interesting case study of a group of species that tend to be

physiologically constrained by environmental extremes (Kearney et al. 2010, Briscoe et al.

2016). Periodic weather extremes have been identified as constraining the ranges of some

Australian mammals (Bateman et al. 2012, Briscoe et al. 2016). Extreme heat can be

particularly challenging for large terrestrial endotherms that must minimise heat gained from

their environment, while also losing heat produced by their own metabolism (Bartholomew

1966). Across Australia high temperatures are often accompanied by low water availability or

high humidity, which can further exacerbate this problem by restricting the use of evaporative

cooling – the primary method of heat loss in most mammal species (Adolph 1947, Maloney

and Dawson 1998). Because Australia's mammal fauna exist across a wide range of

biogeographical regions (from arid zones to tropical environments), there is likely to be some

benefit in studying the group as a whole and seeking generalizations about which types of

extremes constrain their range. Here we provide the first comprehensive account of how

weather extremes constrain the ranges of this diverse group of mammals using a unique

spatial dataset compiled for the purpose. We explore the degree to which SDM predictions

concur under current and future climate and provide recommendations for modellers seeking

robust predictions about species future ranges under changing environmental conditions.

METHODS

Mammals occurrence data

We accessed presence-only records for all terrestrial mammals from the Atlas of Living

Australia (ALA; http://spatial.ala.org.au/). Due to incomplete coverage of all Australian

states, we also sought data from individual states agencies (see acknowledgments). We

filtered and reduced this data set (569,292 records) by: (i) removing gross positional errors on

a basis of contemporary knowledge on current and historical species distribution ranges (Van

Dyck and Strahan 2008, Churchill 2009, Menkhorst and Knight 2010); (ii) retaining only

spatially-valid records collected from 1980 to 2013 with maximum point location error of

less than 1 km and (iii) removing duplicated records: we kept only one observation per

species per grid cell (1 km resolution). We modelled only those species with at least 30

records (n = 197 species) in order to minimize the possible negative influence of small

samples sizes (Hernandez et al. 2006, Wisz et al. 2008). See Appendix S1 for full list of

species and information on data availability for each of them.

Model predictors

Interpolated daily and monthly climate data at 0.05° spatial resolution (~ 5-km) were

obtained from the Australian Water Availability Project for the period 1977 – 2012 (Raupach

et al. 2009, 2012). Temperature data were corrected with an adiabatic lapse rate of 0.00645

°C m^{-1} (Moore 1956, Sturman and Tapper 1996) from the original 0.05° values to a resolution

of 0.01° (~1 km) based on a digital elevation model (DEM) resampled from its original

0.0025° to 0.01° resolution (GEODATA 9-second DEM v.3, Geoscience Australia). The

spatial resolution of the weather data therefore matched the (approximate) worst case on the

spatial point accuracy of the mammals' occurrence data. We used the monthly climate data to

create a set of long-term averaged climatic variables representing mean annual trends (e.g.

142   annual rainfall) and seasonality (e.g. annual range in temperature) using the R package

143   "climates" (version 0.1.1-3) (VanDerWal et al. 2012b). These climate predictors are widely

144   used in species distribution models studies conducted at regional to global scales (Franklin

145   2010).

146   From the daily weather data we calculated seven weather variables accounting for extreme

147   conditions that are likely to influence mammal distributions. These included indices

148   describing the magnitude of temperature extremes (5th and 95th percentile temperatures for

149   minimum and maximum daily temperatures, respectively), maximum length of dry spells

150   (maximum run of sequential dry days; rainfall < 1mm), and rainfall intensity (mean rainfall

151   on days where rainfall >1mm). The effects of hot temperatures on mammals are likely to be

152   dependent on water availability and humidity, which influence the use and effectiveness of

153   evaporative cooling (Adolph 1947, Maloney and Dawson 1998, Krockenberger et al. 2012).

154   Therefore we also calculated mean vapour pressure during hot weather, the maximum length

155   of heatwaves, as well as the sum of temperatures during the longest run of sequential dry

156   days (rainfall <1mm) (see Table 1). All weather and climatic predictors were mapped at 1km

157   grid cell resolution. Models were only based on a subset of the above mentioned variables

158   with maximum Pearson's pairwise correlation of 0.7 (Tabachnick and Fidell 1996, Dormann

159   et al. 2013) (see Table 1 for a description of the retained variables and Appendix S2 for a full

160   list of the variables considered for the analyses and correlation matrices). These correlations

161   were calculated across all mammals' occurrence records of the filtered data set (background

162   points), and assessed for each of the predictor sets individually and jointly.

163   Some remote areas in Central and Western Australia had sparse rainfall data (see Appendix

164   S3) and therefore, interpolation of data in these areas might be insufficient to meaningfully

165   define rainfall patterns in these areas, affecting the calculation of many of the climatic and

166   weather extremes variables explained above. We ran preliminary analyses to identify the

167 boundaries of these sparsely-gauged parts of the continent and to assess the effects of their

168 inclusion into modelling outputs. Areas with sparse station data were masked out of further

169 analysis in order to minimize the effect of these interpolation errors in our subsequent

170 analyses (Appendix S3).

171 In addition to weather variables, a remotely sensed average vegetation height variable was

172 included in all predictors sets (AVG, EXT and COMP) to capture some of the variation

173 relating to underlying habitat type and site productivity (Simard et al. 2011) (Table 1). We

174 chose not to include coarse categorical variables relating to vegetation composition (land

175 cover classes (e.g. National Vegetation Information System of Australia; ESCAVI 2003) due

176 to constraints on the number of observation data points for several species and concerns about

177 over-fitting with categorical variables using numerous degrees of freedom. Note that the

178 vegetation height variable is assumed constant in future predictions due to the lack of

179 information about future distribution of vegetation type and structure, growth, and

180 disturbance.

181 *Modelling framework*

182 We modelled the distribution of mammal species using MaxEnt (version 3.3.3k; Phillips et al.

183 2006, Phillips and Dudík 2008), a machine learning method designed for dealing with

184 presence-only data (Elith et al. 2006, 2011) while taking into account the distribution of

185 environmental predictors in the background area of analysis. For each species we fitted three

186 sets of Maxent models using the average vegetation height predictor plus: (1) the long-term

187 mean climatic variables only (AVG model); (2) the extreme weather variables only (EXT

188 model) and (3) all extreme weather variables plus the long-term averaged annual precipitation

189 (COMP) (see Table 1 for the detailed list of predictors included in each of these predictors

190 sets). This allowed us to test for differences in model predictive performance and spatial

191   predictions of habitat suitability based on long-term mean climatic variables versus extreme

192   weather variables, as well as the effect of using both predictor types in the same model

193   (although, because all temperature related variables were strongly correlated, the only long-

194   term mean climatic variable that could be included in the COMP model was annual

195   precipitation).

196   Exploratory analyses showed that species records were biased towards areas of high

197   accessibility (e.g. roads and urban areas). Biased survey data can lead to environmentally and

198   geographic biased predictions that might reflect the sampling effort rather than the species'

199   true distributions across the study area (Phillips et al. 2009, Kramer-Schadt et al. 2013, Syfert

200   et al. 2013, Lahoz-Monfort et al. 2014). In order to reduce the possible effect of geographical

201   bias in presence data on SDM predictive performance, we provided background points to

202   MaxEnt in such a way as to copy the geographic and environmental bias of the occurrence

203   records (sensu Phillips *et al.*, 2009; Syfert *et al.*, 2013) by using as background all available

204   records for mammals (76,980 records after removing duplicate records per grid cell). This

205   approach, known as the "target-group background" approach (Phillips et al. 2009), has been

206   shown to perform well in dealing with spatial sampling bias (Syfert et al. 2013, Fithian et al.

207   2015). The same background points were used in all three sets of models.

208   In addition to controlling the selection of background points, we also controlled the

209   complexity of the response shapes by allowing only linear, quadratic and product features in

210   the models. These are similar to linear, quadratic and interaction terms in regression models.

211   Models with these restricted feature types will be smoother than those fitted with MaxEnt's

212   default settings, less prone to fitting idiosyncrasies of the data, and potentially better at

213   predicting to new times and places (Merow et al. 2014). Default values were used for all

214   other MaxEnt settings except that adding sample points to the background was not required

215   as that was already achieved by our use of the 'target background' approach. Predictive

216   performance was assessed in terms of discrimination ability measured using the area under

217   the receiver-operator characteristic curve (AUC; Hanley and McNeil 1982) adapted for use

218   with presence - background samples (Phillips et al. 2006). This metric is suited to presence-

219   background data, since calibration cannot be assessed and applying thresholds to predictions

220   loses information (Guillera-Arroita et al. 2015, Morán-Ordóñez et al. 2016). We calculated

221   AUC using the ten-fold cross-validation provided in Maxent. Final reported models were also

222   run using 100 % of the data available for each species. We refer to the later as *'alldata'*

223   models and they were only used to compare future predictions based on the different data sets

224   (AVG, EXT and COMP).

225   *Integration of model results across all species*

226   We used boxplots to analyse the differences in predictive performance (cross-validated AUC)

227   of the three sets of models across all species ($n = 197$). To examine spatial differences in

228   predictions, we calculated the differences in the relative environmental suitability values

229   predicted across the landscape between the three model data sets: $alldata_{EXT} - alldata_{AVG}$,

230    $alldata_{COMP} - alldata_{EXT}$ and $alldata_{COMP} - alldata_{AVG}$. For these analyses, we omitted

231   species for which models performed poorly based on at least one of the three model data sets

232   (cross-validated AUC < 0.7; Swets 1988) as these can not reliably characterise the current

233   distribution of the species ($n = 188$). These comparisons were based on the models fitted

234   with all of the available observation data (i.e. not the cross-validation subsets). This allowed

235   us to identify the areas across the continent where one predictor set predicted higher or lower

236   relative environmental suitability for a given species in comparison with the other model data

237   sets. The difference maps for each species were aggregated across species; providing the

238   mode of the differences across the 188 species for each pair of predictor variable data types

239   (e.g. EXT vs AVG) at each grid cell. This addresses the question of whether the relative

240   suitability of the cell is predicted to decrease or increase at each grid cell for most of the

241   species when fitting the models using EXT predictors compared with AVG predictors. The

242   output of these joint analyses is a binary map showing the areas where the use of one

243   predictor set (e.g. EXT) increases or reduces relative environmental suitability predictions

244   compared with other predictor variable types (e.g. AVG). To explore which variables could

245   be driving the differences in predictions between the two model sets we analysed the

246   distribution of the values of the original predictors in those areas (Table 1).

247   *Future scenarios*

248   To illustrate how the use of different climate variables (EXT, AVG) could influence forecasts

249   of species' responses to climate change, we also predicted mammal distributions for the year

250   2070. Acknowledging the potential importance of GCM variability in analysing the impacts

251   of climate change on biodiversity (Diniz-Filho et al. 2009, Synes and Osborne 2011, Harris et

252   al. 2014) we compared forecasts of species' responses under two general circulation models

253   (GCM), the ACCESS 1.3(CSIRO: Bi et al. 2013) and the CanESM2 -Canadian Earth System

254   Model (Chylek et al. 2011) and the emissions scenario RCP8.5 (Riahi et al. 2011). We

255   modelled future climates under RCP 8.5, a high emissions business as usual scenario, because

256   observed emission trends appear to be tracking these projections (Peters et al. 2013).

257   Relative to other possible futures, the ACCESS 1.3 scenario modelled here represents a

258   relatively hot and dry climate future for Australia, with CanESM2 predicting more variable

259   changes in rainfall across the continent. Downscaled projected monthly changes in

260   temperature, humidity, and rainfall for 2070 were obtained as the differences from the base

261   period (1990-2009) using SimClim (1 km resolution; Yin et al. 2013) and assuming

262   greenhouse gas concentrations for RCP8.5 and a moderate response to increased CO_2

263   concentrations (Riahi et al. 2011). We then used the offset (or change factor) method to

264   construct future daily weather data by combining the change signal from these GCM outputs

11

265   with observed weather datasets (CSIRO and Bureau of Meteorology 2015), an approach

266   previously used in impact assessments (Cullen et al. 2009, Bell et al. 2012). At each site we

267   splined predicted monthly changes in temperature and humidity to predict daily changes over

268   an annual cycle, with these then added to daily weather data for 1990-2009. To generate

269   rainfall predictions we applied the monthly predicted changes in total precipitation to

270   observed monthly rainfall values (1990-2009), with the constraint that monthly rainfall could

271   not fall below 0. We then multiplied rainfall from all of the days with rainfall greater than 0

272   by a set proportion, such that the new monthly total rainfall matched predictions. Changes in

273   the temporal pattern of 'rainy days' were therefore driven by changes in rainfall that resulted

274   in days that were previously classified as 'rainy days' being classified as 'dry days' (i.e. if

275   rainfall fells below 1mm) and vice versa. While climate change may also alter rainfall

276   patterns, for example by increasing the frequency of heavy rainfall events followed by longer

277   dry spells, spatial and temporal predictions of how changes in variance are likely to influence

278   patterns of daily weather and extremes across all of Australia were not available at the time of

279   our study. Future climate average and extreme weather variables were then calculated from

280   these derived daily future weather data.

281   Long-term averaged and short-term extreme weather variables were used to generate

282   predictions of mammal distributions for 2070 using the three sets of MaxEnt models fitted

283   under the current climate (AVG model, EXT model and COMP). We compared the spatial

284   predictions of AVG, EXT and COMP model projections for the current and 2070 climates

285   and measured the correlations between their spatial outputs, and the extent of predicted

286   temporal change in suitable ranges (calculated as the sum of cell values of the logistic

287   MaxEnt output across Australia). We used the limiting factors tool of MaxEnt (Elith et al.

288   2010) to explore which variables limit the predicted geographic distribution of mammals the

289   most both currently and under the 2070 climatic/weather scenarios. This tool identifies the

290   variable *X* that could increase environmental suitability the most at a given grid cell when its

291   actual value is changed by its mean value across the training data. We also used the MESS

292   map tool of MaxEnt (Multivariate Environmental Similarity Surface; Elith et al. 2010) to

293   assess the proportion of novel environmental space in each model prediction, under both

294   current and future scenarios (i.e. the level of environmental extrapolation). We calculated the

295   percentage of grid cells across Australia with values outside the environmental ranges

296   captured by the target-group background data used to fit the models. All statistical analyses

297   were performed in R (R Core Team 2013).

298   We also explored whether the differences in spatial predictions of AVG, EXT and COMP

299   model projections for current and 2070 climates were related to species traits. We collated

300   available trait data for the mammal species modelled (body mass, activity cycle and

301   geographic breath) and plotted the relationship between these traits and the aspects of model

302   prediction evaluated here (correlations between spatial output predictions and differences in

303   predicted ranges). In addition, we assessed whether differences in range projections varied

304   between species occupying different primary climatic zone/s.

305   **RESULTS**

306   There was a relatively high correlation between predictions, and high congruence in

307   predictive discrimination between modelling approaches based on average, extreme and

308   composite climate variables. However, the relatively high correlation between predictions

309   broke down when predicting to future climates due to the divergence in spatial patterns of

310   average and extreme climate predictors.

Current distributions

312   The predictive discrimination of models tested using cross-validation did not differ markedly

313   between the three sets of climatic/weather scenarios (AVG, EXT and COMP), with moderate

314   to high predictive performance across most species (AUC $\geq$ 0.7; Fig. 1). Only 9 out of 197

315   mammal species showed poor predictive performance across at least one scenario (AUC <

316   0.7; Appendix S1). These nine species had low predictive performance across all three

317   variable sets, and were not considered for subsequent analyses.

318   For many species predictions of environmental suitability differed spatially between models

319   that utilized different predictor variables. Models fit using averaged short-term extreme

320   weather predictors (EXT) predicted higher environmental suitability compared to models fit

321   using long-term averaged climatic predictors (AVG) for most species across Tasmania, the

322   SE and SW parts of continental Australia, as well as some small areas in the NE coast of

323   Australia (Fig. 2a, b). Areas where higher environmental suitability was predicted by the

324   extremes models for the largest number of species (areas with darker colours in Fig. 2a), are

325   characterized by either their low average annual mean temperature (< 10 ºC; Fig 2c), very

326   low - < 5th percentile - minimum temperatures (< -5 ºC; Fig 2g), high rainfall (> 2000 mm;

327   2f), high vegetation height (> 40 m) and/or for being areas where the contrast between the

328   diurnal temperature range differs markedly from the annual temperature (isothermality values

329   < 0.4; Fig. 2d). The areas where lower environmental suitability was predicted for the largest

330   number of species when using extreme weather predictors instead of long-term average

331   climatic predictors (areas with lighter colours in Fig 2a and grey areas in Fig 2b) were

332   characterized by one or more of the following conditions: high average annual mean

333   temperatures ($\geq$ 25 º C; Fig 2c); high 5th percentile minimum temperatures ($\geq$ 10 º C, tropical

334   and subtropical regions; Fig 2g); areas where there is either very high humidity or very low

335   humidity during hot weather (tropical and arid zones, respectively; Fig 2h); areas that

336   experience very high temperatures over long dry spells (areas in the Central and NW of

337   Australia; Fig. 2i, j); and areas with low seasonality (Fig 2e) where the diurnal temperature

338   range does not differ much from the annual temperature range (mainly the tropical regions of

339   the North of Australia; Fig 2d).

340   Models fit on short-term extreme weather conditions *plus* annual rainfall (COMP) showed

341   very similar spatial patterns to models fit on extreme weather conditions only (EXT).

342   Therefore, the comparison between COMP and AVG models yields near identical results to

343   the comparison between EXT and AVG models (Appendix 4, Fig. S4.1). However, COMP

344   models predicted a decrease in environmental suitability compared to EXT models for most

345   species in areas with high annual rainfall (mainly the Western Coast of Tasmania and the NE

346   coastal areas of continental Australia) and an increase in environmental suitability in the NW

347   of Australia (Appendix S4, Fig. S4.2).

348   *Current vs future distribution predictions*

349   We found that the relationship between averages and extreme weather variable models were

350   very similar under both GCM scenarios (Appendix S5). Thus, for simplicity, and because we

351   are interested in exploring the variation in predictions due to the variables set selection rather

352   than the variation associated to different GCM scenarios, we focus here on the results from

353   simulations using one scenario only (ACCESS 1.3).

354   In general, Pearson's correlations between environmental suitability maps of AVG, EXT and

355   COMP models were lower under the *2070* hot and dry climate scenario than under *current*

356   climate/weather, suggesting a divergence in predictions of environmental suitability under

357   future climate change (Fig. 3a, Fig. 4). These results were consistent even when assessed only

358   within the extent of the biogeographical regions where the species is known to occur

359   currently (Appendix S6). For most of the species the decrease in correlations between *current*

360   and *2070* climate scenarios was less than |0.2| across all predictor sets (Fig 3b). However, for

361   13 of the 188 species modelled, Pearson's correlations between environmental suitability

362   maps dropped from r >0.6 (highly correlated) to r < 0.36 (weakly correlated) under the 2070

363   climate scenario when comparing EXT vs AVG models, and for 19 species when comparing

364   COMP vs AVG models (Fig. 3a, b).

365   Across the 13 species that showed large declines in correlations between current future

366   scenarios, future divergences were most commonly due to the fact that the EXT and COMP

367   models predicted large changes in distribution relative to the AVG model predictions

368   (Appendix S7). For example, environmental suitability predictions for the Paucident

369   Planigale (*Planigale gilensy*) were similar between AVG, EXT and COMP models under

370   current climate (all models identified the central parts of the continent as the most suitable for

371   this species) (Fig. 4). In contrast, whereas the AVG model predicted that areas predicted to be

372   suitable for the Planigale under the current climate would remain suitable under the 2070

373   climatic scenario, EXT and COMP models predicted dramatic shifts in the distribution range

374   of the species in slightly different directions (from central Australia towards the South and

375   South-East coast; Fig. 4). For this species, the shifts in the suitable conditions predicted by

376   EXT and COMP models seem to be driven by the increase in the length of heatwaves

377   (*av.m0v.hot*) predicted under the 2070 scenario (Fig. 4). In some other cases, the change in

378   predictions' correlations over future scenarios arises because one of the predictor-set models

379   predicted limited or zero environmental suitability for a species under 2070 scenario whereas

380   other models predicted the maintenance of the suitable environmental range over time or

381   even an increase in environmental suitability (see further examples in Appendix S7).

382   In general terms, under the *current* climate scenario the extent of suitability predicted by

383   EXT and COMP models tended to be smaller than those predicted by AVG models, although

384   this difference was not evident when we included only biogeographical regions where the

16

385　species is known to occur currently (Fig. 5, Fig. S6 d, f). Under the *current* climate COMP

386　models predicted slightly more restricted suitable distribution ranges than EXT models (Fig

387　5). Under the *future* climate scenario, differences in the extent of predicted suitable range

388　showed a high variability across species and predictors sets.

389　The amount of extrapolation to novel environments (as measured by MESS maps) was larger

390　in EXT and COMP models than in AVG models under both current and - especially- future

391　climate scenarios. Under the current climate, novel climatic conditions were found in 0.08,

392　0.11 and 0.12% of the total study area for AVG, EXT and COMP predictions, respectively.

393　These percentages increased to 20.6, 57.8 and 59.9 %, respectively under the future climatic

394　scenario. The areas of non-analogue climate under the future scenario are located mainly in

395　the Central and Northern parts of the continent (Appendix S8).

396　We found no clear evidence for an effect of species traits on the magnitude of divergence of

397　predictions between AVG, EXT and COMP models (Appendix S9). The reduction in

398　suitable range predicted by EXT models compared to AVG model under future climate

399　scenario was marginally larger for species that occupy - totally or partially- desert areas or

400　areas of hot and dry summers and mild winters (Fig. S9.1) than for species characteristic of

401　other climate zones.

402　**DISCUSSION**

403　Conservation of species under climate change relies on accurate predictions of both the extent

404　and suitability of species ranges under current and future climate conditions. We showed that

405　species distribution models based on long-term averaged means and extreme conditions

406　generally have similarly good predictive performance, and yet predicted geographic ranges

407　for the same species often differ (both in extent and spatial distribution). Differences in the

408　spatial predictions of these models increase under future climate scenarios (Fig. 4, Appendix

409 S7). These differences are likely to have significant implications for conservation, such as

410 leading to different spatial priorities for conservation actions, and in extreme instances,

411 influencing extinction risk status assessment under IUCN red list or other prioritization

412 approaches. Our results highlight the importance of accounting for extreme conditions/events

413 alongside traditionally used long-term averaged climatic predictor when modelling species

414 distributions on the basis of their climatic niche. Failure to consider the potential role of

415 extreme conditions when modelling species distributions could lead to unreliable predictions

416 of species responses to change in climate.

417 Across species, EXT and COMP models tended to predict more restrictive suitable ranges

418 than AVG models suggesting that extreme weather conditions might limit species

419 distributions in areas theoretically suitable in terms of long-term mean climatic conditions. In

420 other words, models based on long-term averages might be over predicting the amount of

421 environmental suitable area for a species, at least in some areas (Zimmermann et al. 2009,

422 Reside et al. 2010, Bateman et al. 2012, 2016, Briscoe et al. 2016). Divergences between

423 model predictions showed strong patterns in geographic and environmental space (Appendix

424 S7), providing general insight into key processes that may be missed by failing to consider a

425 broad suite of climate variables. Based on annual mean temperature values (AVG models)

426 many species that occur in temperate areas along the East coast of Australia were predicted to

427 also find suitable environmental conditions in the arid central parts of the continent and/or in

428 the subtropical or tropical northern areas under the current climate scenario. Although these

429 areas may not differ substantially in mean climate, they are likely to present quite different

430 challenges to mammal species. For example, mammals that rely heavily on evaporative

431 cooling may struggle to regulate their body temperature when faced with high temperatures

432 coupled with high humidity – conditions that frequently occur in subtropical and tropical

433 areas (Adolph 1947, West 2003, Briscoe et al. 2016). Similarly, the arid zones of central and

434 northern Australia are challenging for species that do not have physiological or behavioural

435 adaptations (e.g. heterothermy, use of burrows, nocturnality) to cope with long heatwaves or

436 extended dry spells captured in the EXT model thorough the variables *av.sum.temp* and

437 *av.m0v.hot* (Fuller et al. 2014). While we found no strong patterns between the divergence of

438 predictions between different models and a number key species' traits, we did find that range

439 predictions in the future tended to diverge more for species that occupied environments

440 characterised by these conditions (e.g. desert and areas with hot summers/mild winters).

441 Models based on extreme conditions only (EXT) predicted higher suitability for species than

442 AVG models in areas of very high annual rainfall (mainly areas corresponding to the

443 distribution of rainforest in Australia) and areas characterized by low minimum (temperatures

444 below 5th percentile) and average annual mean temperatures. This might be due to the fact the

445 variables included in the EXT model focused on capturing extreme conditions that are likely

446 to prove physiologically challenging for mammals. These variables may fail to capture

447 processes responsible of the distribution of vegetation communities and their productivity

448 over space and time (which in turn determine patterns of species distributions and richness),

449 such as the cumulative effect of rainfall over time in combination with annual mean

450 temperatures (Huston and Wolverton 2009). These factors were better captured in the AVG

451 model (annual mean temperature is known to be a good proxy for net primary productivity;

452 Gaston 2000, Huston and Wolverton 2009) and therefore in their absence, EXT models might

453 have overestimated the suitability of some areas for many species. For example, mountain

454 areas in the South Eastern Great Dividing Range will have similar values of T5 (extreme

455 minimum temperatures) than neighbouring temperate or semi-arid inland areas, yet their

456 annual mean temperature and total rainfall – and therefore the vegetation communities and

457 species they support – differ substantially (e.g. dense forest in the Great Dividing Range vs

458 open dry woodlands). Ideally, both extreme conditions and long-term averages should be

19

459 considered together as potential predictors for species distribution models (e.g. COMP

460 models in this study), since each individual extreme and average climatic variable might help

461 to capture different aspects of the ecology and distribution of the species over different spatial

462 scales. This is supported by the fact that in our study, COMP models tended to perform

463 slightly better than either EXT or AVG models (although we note that they did also have one

464 extra predictor variable, which may have had a minor influence on results). However, there

465 are potential drawbacks of integrating all these variables in the same model: many of the

466 extreme weather conditions are strongly correlated to long-term averages under the current

467 conditions (Appendix S2), and the inclusion of correlated variables might hamper the

468 capacity of using these models for inference (James et al. 2013). Model averaging or

469 ensemble modelling approaches may prove useful as a way of capturing multiple processes in

470 inference and prediction (Wintle et al. 2003, Thuiller et al. 2009) while avoiding parameter

471 instability during model fitting.

472 Correlations between extreme variables and average conditions are expected to change over

473 space and time: recent studies have demonstrated that extremes of temperature and

474 precipitation are changing at a faster rate than annual trends (Alexander et al. 2007). This

475 might help explain why spatial predictions –and therefore correlations - between different

476 models diverged more under the future climatic scenario tested here than under the current

477 climate. Divergence in EXT, COMP and AVG future model predictions is also associated

478 with the fact that more than 50 % of the extreme conditions predicted for 2070 showed non-

479 analogue conditions under current climate (i.e. there is a large uncertainty of predictions in

480 more than 50 % of Australia). The extrapolation of predictions to non-analogue

481 environmental conditions in MaxEnt is controlled by a feature called "clamping": it

482 constrains predictions to remain within the range of values of the training data (in the case of

483 this study, the target-group background data set used to characterize the range of available

484   environmental conditions under current climate) (Elith et al. 2011). Therefore, the prediction

485   of environmental suitability in areas of non-analogue climate is constant. In our simulations,

486   non-analogue conditions for EXT models were largely driven by longer runs of hot days

487   (*av.m0v.hot*) than observed under the current climate. In many instances, the relative

488   environmental suitability for species' was close to zero at the maximum values of *av.m0v.hot*

489   under the current climate, supporting the use of the 'clamping' feature. These predictions do

490   not explicitly take into account the physiological thresholds of the species (which in most

491   cases is unknown as it requires detailed studies/lab experiments not available for most of the

492   species; Krockenberger et al. 2012) nor the resilience and plasticity of the species to adapt to

493   changes in environmental conditions (Elith and Leathwick 2009, Catullo et al. 2015). For

494   example, model predictions for the species *Rhinonicteris aurantia* , the Orange leaf-nose bat

495   using EXT and COMP predictors sets showed that there would not be any climatic suitable

496   conditions for the species in a hot and drier Australia in 2070 (Appendix S7). However this

497   species roosts in cave environments that are strongly buffered against daily, seasonal and

498   long-term variations in external climatic conditions (i.e. environments with relatively

499   constant temperature and humidity). Therefore, the 2070 predictions of EXT and COMP

500   models might not correspond to the real conditions that the species will experience in a hot

501   and drier climate future.

502   Our finding that models with apparently similar predictive performance when evaluated

503   against current observation data can diverge so much when projected to future climates has

504   significant implications for the way predictive uncertainty should be represented and results

505   used in conservation decision making. The use of extreme weather variables known to

506   directly impact species or groups of species (mammals in this case) when making predictions

507   of future species ranges, permits identification of areas in the landscape where species will be

508   more or less at threat by extreme weather. This helps identify future climatic refugia where

509   species could be buffered against extreme events, providing greater chances of adapting to

510   long-term changes in average climatic conditions (Reside et al. 2014). However, very few

511   studies that analyse the long-term prospects for species under climate change account for the

512   potential effect of extreme weather conditions. This may be partly due to the fact that,

513   relative to data on future mean climate, projections of extremes (e.g. length of heatwaves or

514   dry days) are much less commonly available (Garcia et al. 2014). The uncertainty arising

515   from having to choose between models - e.g. model types or model predictors - is almost

516   never represented as prediction uncertainty or formally considered when assessing

517   conservation options (sensu Moilanen and Wintle 2006). Our results highlight the importance

518   of incorporating uncertainty about predictor choice when representing SDM prediction

519   uncertainty and interpreting the results of climate change impact studies. For several species

520   in this study that appeared to be modelled quite well based on current data (high AUCs, high

521   deviance reduction), the predicted 2070 distributions ranged from total loss of suitable range

522   through to a substantial increase in range, depending on which climate or weather variables

523   were included in the model. There remain significant challenges in interpreting and acting on

524   such results that will require both further validation data (species presence-absence data –

525   which is more robust than presence-only data for evaluating predictions, but rarely available

526   at large spatial scales for most taxa) and sophisticated decision support approaches to

527   explicitly factor in predictive uncertainty. It is well understood that choosing a single-best

528   model for inference and prediction about the future of a species is a risky strategy (Wintle et

529   al. 2003, Thuiller et al. 2009). We advocate for thoughtful application of multi-model

530   inference and treatment of model-choice uncertainty when predicting the future distribution

531   of a species and planning for the conservation of species in a rapidly changing world.

748   **Table 1.**

749   Environmental predictors retained for modelling. A check mark denotes the predictors included in each of the predictors sets used to fit the
750   species distribution models: the long-term mean climatic variables only (AVG model; five predictors); the extreme weather variables only (EXT
751   model; five predictors) and all extreme weather variables plus the long-term averaged annual precipitation (COMP; six predictors)

Variable name		Description	Resolution	AVG	EXT	COMP
Climate: averages						
Bio1		Annual Mean Temperature	0.05°	✓		
Bio3		Isothermality: mean diurnal range /annual temperature range	0.05°	✓		
Bio4		Temperature Seasonality (standard deviation)	0.05°	✓		
Bio12		Total annual Precipitation	0.05°	✓		✓
Weather: extremes						
T5		5th percentile of minimum temperature (across all years)	0.05°		✓	✓
av.vpr.hot	Average vapour pressure on days when maximum temperature exceeds T90 (maximum temperature > 90th percentile)	0.05°		✓	✓
av.sum.temp	Sum of maximum temperatures during maximum run of dry days (rainfall < 1mm), (average across years)	0.05°		✓	✓
av.m0v.hot	Maximum run of hot, dry days (maximum temp >T90, rainfall <1mm) (average across years)	0.05°		✓	✓
Vegetation structure						
veg.hgt		Forest canopy height (Simard *et al.*, 2011)	1 km	✓	✓	✓

752

Figure 1. Notched boxplots for AUC values (area under the curve statistic) for all cross-validated mammals' models (n= 197 species), detailed for climate/weather predictor-set: AVG (models using long-term averaged climatic conditions), EXT (averaged short-term extreme weather conditions) and COMP (averaged short-term extreme weather conditions plus long-term average annual rainfall). In each boxplot, the boxes delimit interquartile ranges (25th and 75th percentiles), the whiskers delimit ~2 standard deviations. The notches are centred around the AUC median values (horizontal bolded line) and the outliers are represented as open circles. The lack of overlap between the notch - narrowing around the median - of two boxes offers evidence of a statistically significant difference between the medians. Note that the Y-axis is truncated to the range of observed AUC values (0.6 - 1).

Figure 2. a) Spatial variation in the number of species for which models fit using short-term extreme weather conditions (EXT) predicted higher habitat suitability than models fit using long-term averaged climatic conditions (AVG); **b)** Difference between spatial predictions of EXT and AVG models. Areas of the continent where EXT models predict higher environmental suitability than AVG models for most of the species are shown in orange, with regions where EXT models predict lower environmental suitability than AVG models for most species shown in grey; **c - k)** Density plots for the predictors used to fit EXT and/or AVG models (see Table 1 for a full description of these predictors). These plots (c –k) show the range of values of each predictor in each one of the two zones defined in Figure 2b, and the frequency at which those values occur across the landscape: the orange curve shows the distribution of the predictors' values in the areas where EXT models predict higher environmental suitability compared to AVG models for most of the species; the grey curve shows the distribution of predictors' values in the areas where EXT models predict lower environmental suitability compared to AVG models for most of the species. Arrows point to

areas of the environmental space where the values of predictors contribute to explain the differences in spatial predictions of EXT and AVG models.

Figure 3. **a)** Pearson's correlations between the environmental suitability maps of models fit on the three predictor-sets (AVG, EXT and COMP), under current climatic/weather conditions (current scenario– x-axis) and under a hot and dry climate future scenario for 2070 (2070 scenario – y-axis); points aligned to the dashed black line indicate species for which the correlation between environmental suitability maps was constant over current and 2070 climatic scenarios; **b)** Range of changes in Pearson's correlations of environmental suitability maps between 2070 and current climates (X-axis) for each pair of predictor sets (EXT vs AVG, COMP vs AVG and COMP vs EXT). The Y-axis indicates the frequency (number of species) at which those changes in correlation were observed across the data (n=188 mammal species). Composite (COMP) and extreme-only model predictions for 2070 are, on average, more highly correlated than composite and long-term-average predictions, reflecting that extremes variables are contributing more to composite models than the long-term-average variables.

Figure 4. Environmental suitability maps for the Paucident Planigale (*Planigale gilesi*) as predicted by each climate predictor set (AVG, EXT and COMP). Predictive performance values (cross-validated AUC value, mean±sd) are indicated for the current predictions of each model. The figure shows the contrast between the predictions of each predictor-set under current and future (2070) climatic scenarios (maps on first and second columns, respectively). The limiting factors maps (third column) show the variable that it is limiting the most an increase in environmental suitability at each grill cell and across the study area under the 2070 scenario and for each climate predictor-set individually (AVG, EXT and COMP). Refer to Table 1 for meaning of the variables' abbreviations.

Figure 5. Differences in the predicted environmental suitability range between the three predictor-sets (AVG, EXT and COMP) for current climate scenarios (current scenario– x-axis) for a hot and dry climate 2070 future scenario (2070 scenario– y- axis). Environmental suitability range was calculated as the sum of grid values of the logistic MaxEnt output across Australia. When comparing EXT vs AVG, positive values in any of the axis indicate that the total range predicted by EXT models is larger than the range predicted by the AVG models, and negative values indicate the opposite. Similarly for the COMP vs AVG and the COMP vs EXT comparisons. The intersection between the two dashed black lines represents a species for which there was no difference in predicted suitable range between models under either current or 2070 (future) scenarios.

Appendix 2. List of predictors and table of Pearson's correlations (correlations > 0.7 are shaded in grey).

Variable name	Description
Long-term average climatic predictors (AVG)	
Bio1	Annual Mean Temperature
Bio2	Mean Diurnal Range
Bio3	Isothermality: mean diurnal range /annual temperature range
Bio4	Temperature Seasonality (standard deviation)
Bio5	Max Temperature of Warmest Period
Bio6	Min Temperature of Coldest Period
Bio7	Temperature Annual Range
Bio8	Mean Temperature of Wettest Quarter
Bio9	Mean Temperature of Driest Quarter
Bio10	Mean Temperature of Warmest Quarter
Bio11	Mean Temperature of Coldest Quarter
Bio12	Annual Precipitation
Bio13	Precipitation of Wettest Period
Bio14	Precipitation of Wettest Period
Bio15	Precipitation Seasonality (coefficient of variation)
Bio16	Precipitation of Wettest Quarter
Bio 17	Precipitation of Driest Quarter
Bio18	Precipitation of Warmest Quarter
Bio19	Precipitation of Coldest Quarter
Extreme climatic and weather conditions (EXT)	
T5	5th percentile of minimum temperature (across all years)
T95	95th percentile of maximum temperature (across all years)
av.vpr.hot	Average vapour pressure on days when maximum temperature exceeds T90
av.m0v.dry	Average maximum run of dry days
av.rr.int	Rainfall intensity (mean rainfall on days where rainfall >1mm)
av.sum.temp	Average sum of temperatures during maximum run of dry days
av.m0v.hot	Average maximum run of hot (maximum temp >T90) days that it doesn't rain
Vegetation structure	
veg.hgt	Forest canopy height (Simard et al. 2011)

Appendix 3. Spatial distribution of meteorological stations across Australia.

Meteorological stations with daily and monthly rainfall observations across Australia (green squares in the map). The dashed polygon indicate the area that was masked out of the analyses due to sparse daily weather data. Source: Bureau of Meteorology, Australian Government (http://www.bom.gov.au/climate/averages/).

Appendix 4. Comparison between spatial outputs of different predictor sets

COMP vs. AVG
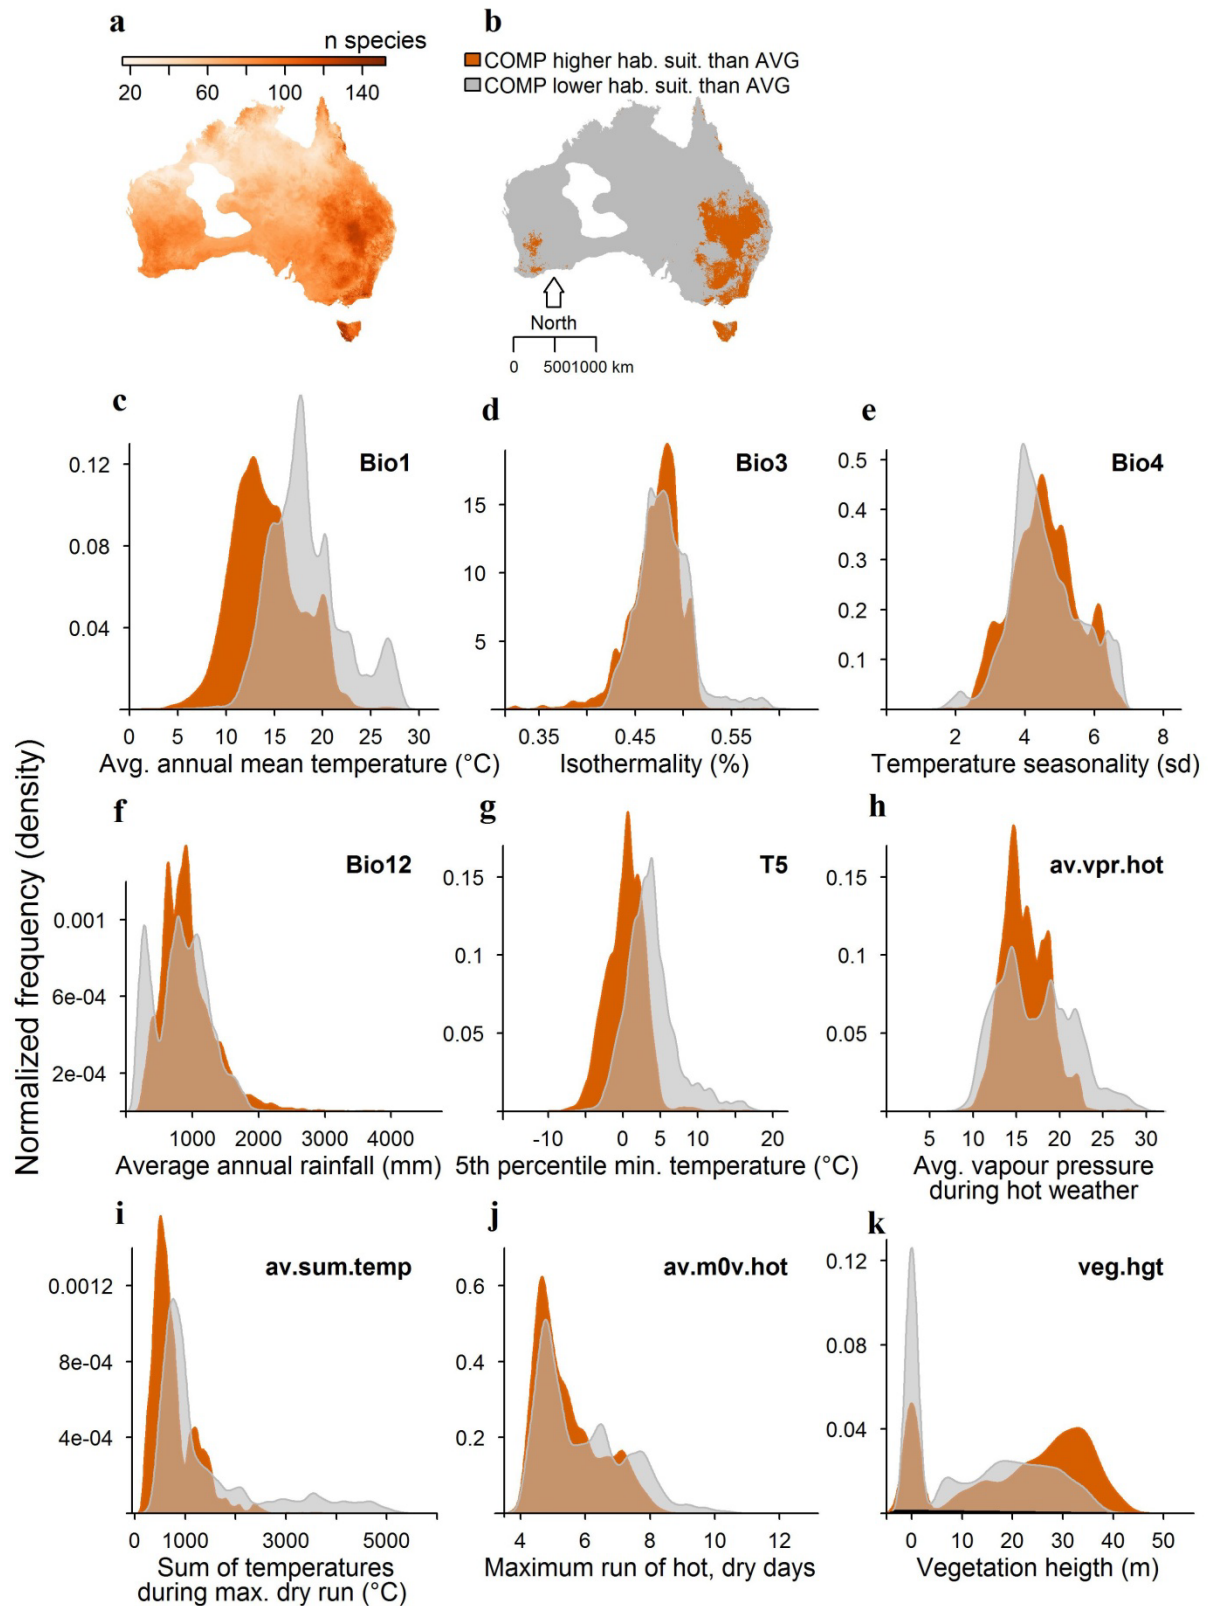

Figure A4.1 Difference between spatial predictions of models fit using short-term extreme weather conditions plus annual rainfall (COMP) and models fit using long-term averaged climatic conditions only (AVG). See caption of Figure 2 in the main text for a full explanation of plots' meaning.

COMP vs. EXT
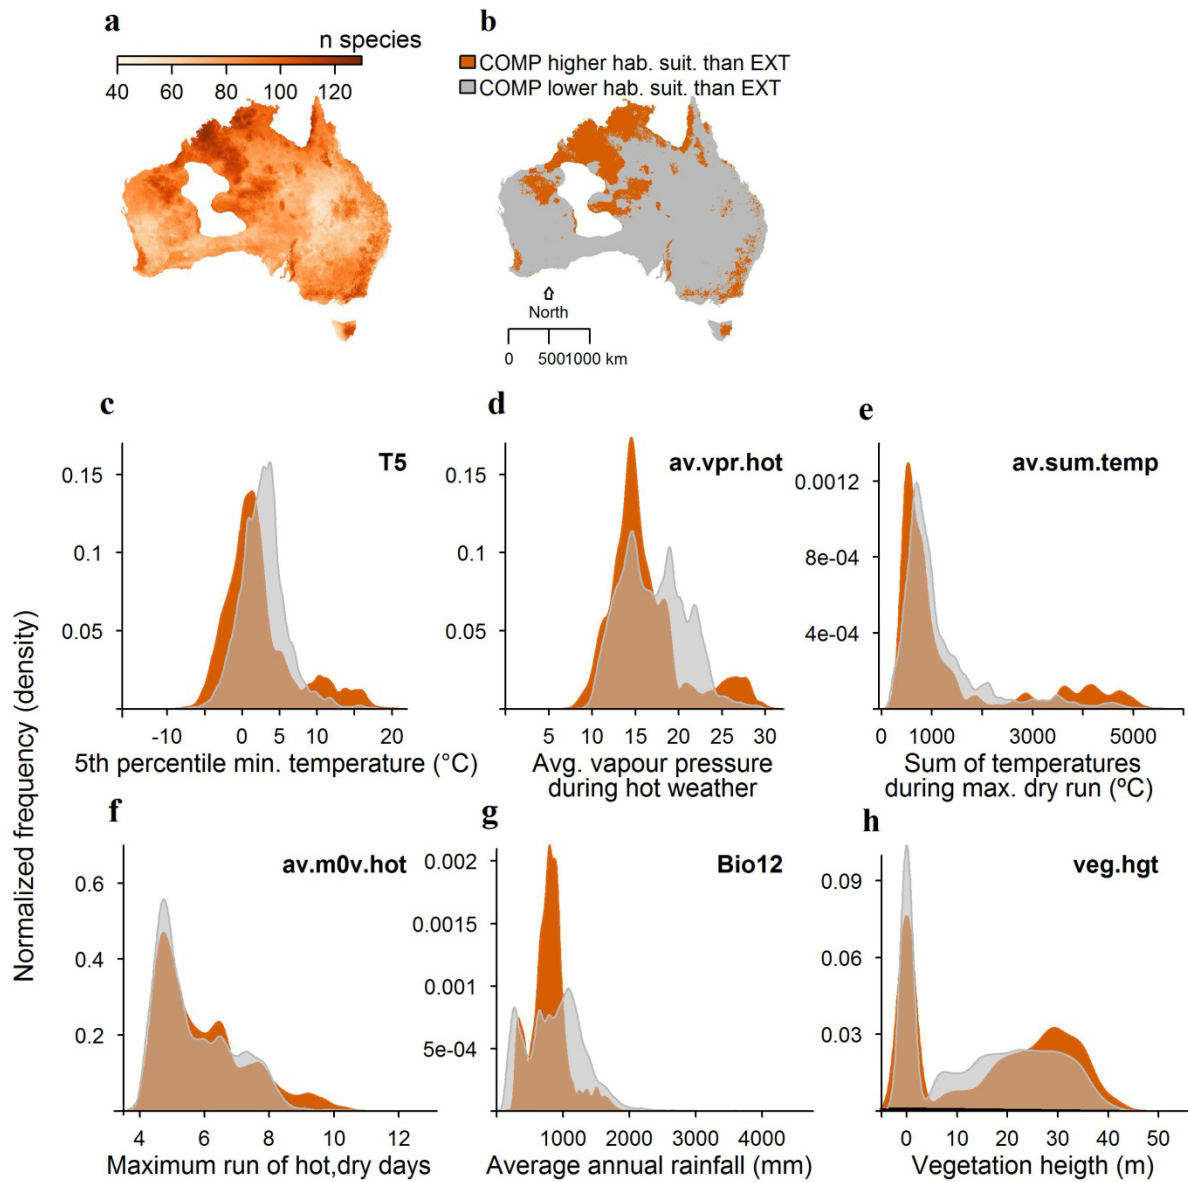

Figure A4.2 Difference between spatial predictions of models fit using short-term extreme weather conditions plus annual rainfall (COMP) and models fit using long-term averaged climatic conditions only (EXT). See caption of Figure 2 in the main text for a full explanation of plots' meaning.

Appendix 5 Comparison of results under the CanESM2 -Canadian Earth System Model – and the ACCESS 1.3 emissions scenarios
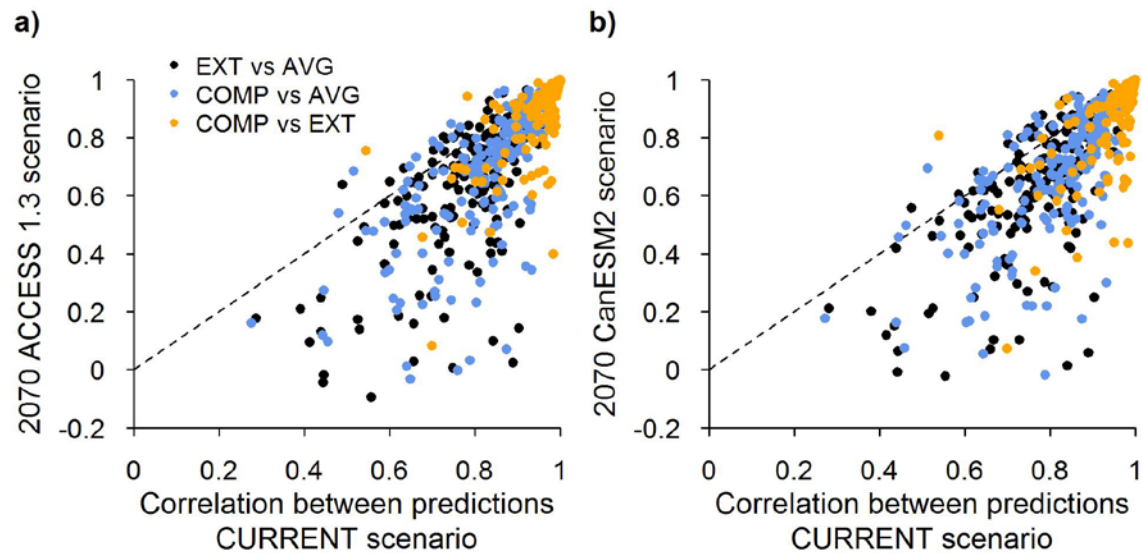

Fig. A5.1. Pearson's correlations between the habitat suitability maps of models fit using the three predictor-sets (AVG, EXT and COMP), under current climatic/weather conditions (*current* scenario– x-axis) and under **a) ACCESS 1.3**. future scenario for 2070 (same figure as Figure 3a in main text) and **b) CanESM2** -Canadian Earth System Model- future scenario for 2070; points aligned to the dashed black line indicate species for which the correlation between its habitat suitability maps was constant over *current* and *2070* climatic scenarios.
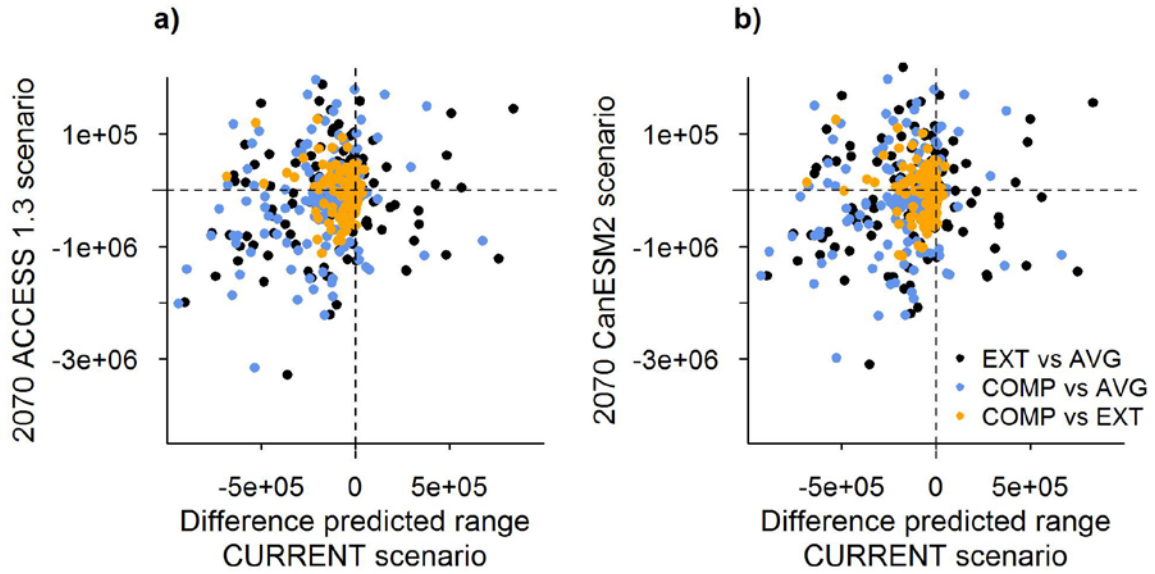

Fig. A5.2. Differences in the predicted habitat suitability range between the three predictor-sets (AVG, EXT and COMP) in the current climate scenarios (*current* scenario– x-axis) and in **a) ACCESS 1.3**. future scenario for 2070 (*y*- axis) (same figure than Figure 5in main text) and **b) CanESM2** -Canadian Earth System Model- future scenario for 2070 (y- axis). Habitat suitability range was calculated as the sum of grid values of the logistic Maxent output across Australia. When comparing EXT vs AVG, positive values in any of the axis indicate that the total range predicted by EXT models is larger than the range predicted by the AVG models, and negative values indicate the opposite. Similarly for the COMP vs AVG and the COMP vs EXT comparisons. The intersection between the two dashed black lines represents a species for which there was no difference in predicted suitable range between models under either *current* or *2070* (future) scenarios.
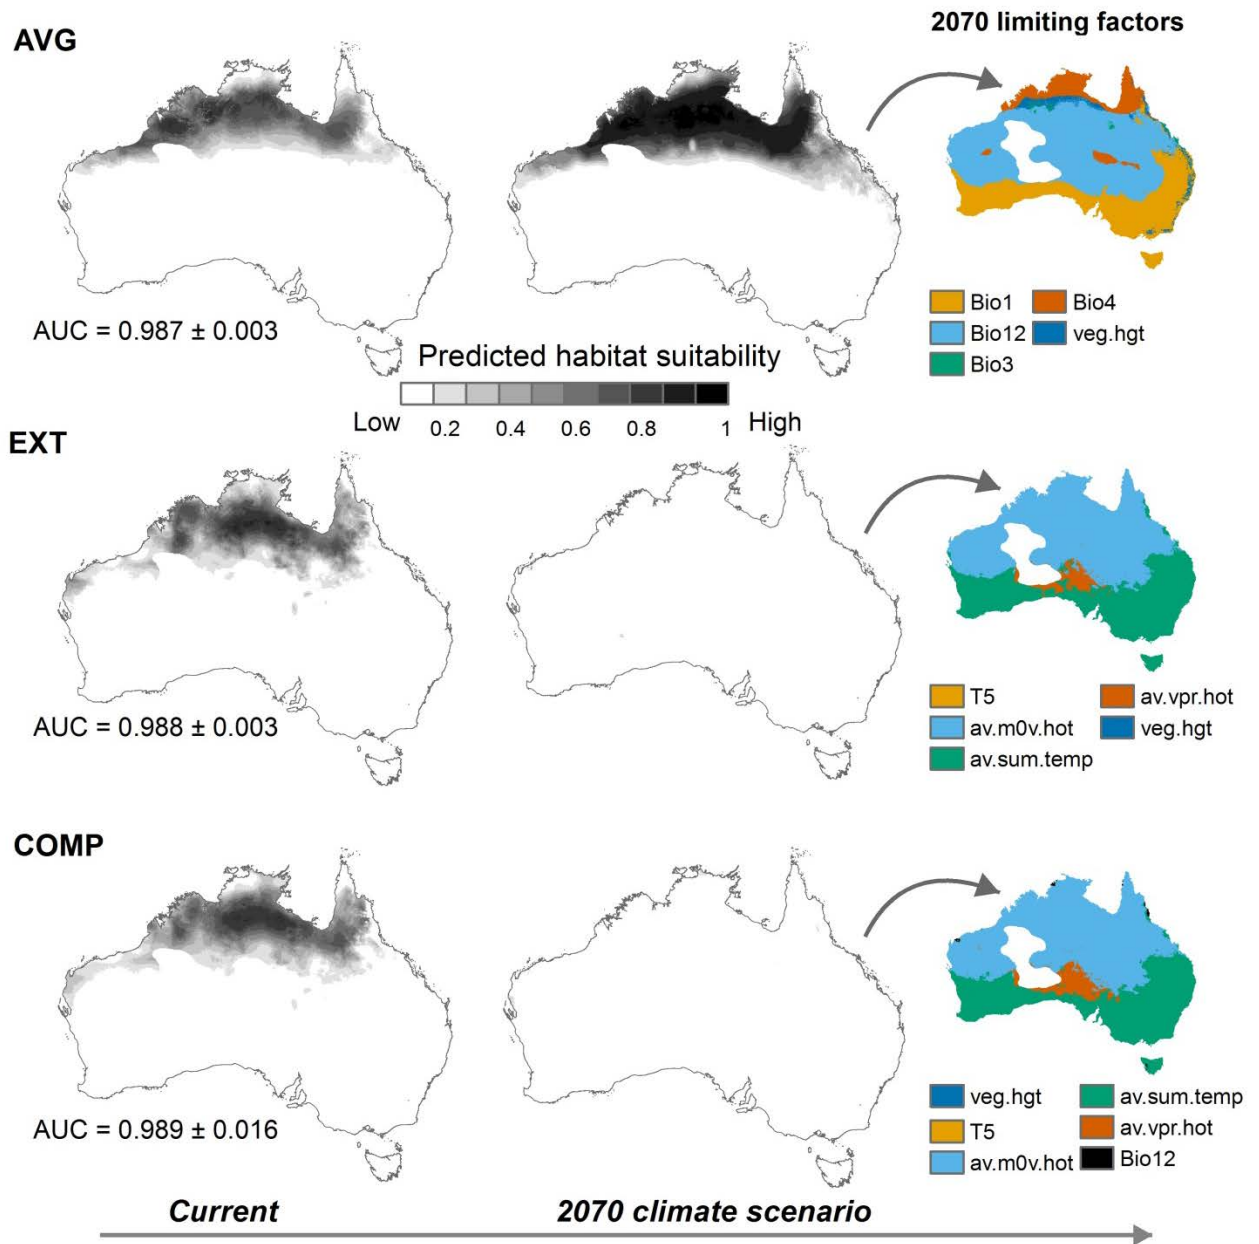

Appendix 6. Change in correlations and range predictions between model outputs overtime.

Figure A6 compares results of model predictions when these were assessed at three different spatial extents: (1) Australia wide (panels a, b); (2) the biogeographic regions where each species occurred – based on training presence data- (Biogeographic regions; panels c, d) and (3) the biogeographic regions where each species occurred and their directly neighbouring biogeographic regions (Biogeographic regions extended, panels e, f). We used the Interim Biogeographic Regionalisation of Australia spatial layer (IBRA v 7), to identify the biogeographic regions where there were occurrence records of each species as their extent and geographic distribution (http://www.environment.gov.au/land/nrs/science/ibra).

Panels a, c, e show Pearson's correlations between the habitat suitability maps of models fit using the three predictor-sets (AVG, EXT and COMP), under current climatic/weather conditions (current scenario– x-axis) and under a hot and dry climate future scenario for 2070 (2070 scenario – y-axis); points aligned to the dashed black line indicate species for which the correlation between its habitat suitability maps was constant over current and 2070 climatic scenarios.

Panels b, d, f show the differences in the predicted habitat suitability range between the three predictor-sets (AVG, EXT and COMP) for current climate scenarios (*current* scenario– x-axis) for a hot and dry climate 2070 future scenario (*2070* scenario– y- axis). Habitat suitability range was calculated as the sum of grid values of the logistic Maxent output across Australia. When comparing EXT vs AVG, positive values in any of the axis indicate that the total range predicted by EXT models is larger than the range predicted by the AVG models, and negative values indicate the opposite. Similarly for COMP vs AVG and COMP vs EXT comparisons. The intersection between the two dashed black lines represents a species for which there was no difference in predicted suitable range between models under either *current* or *2070* (future) scenarios.
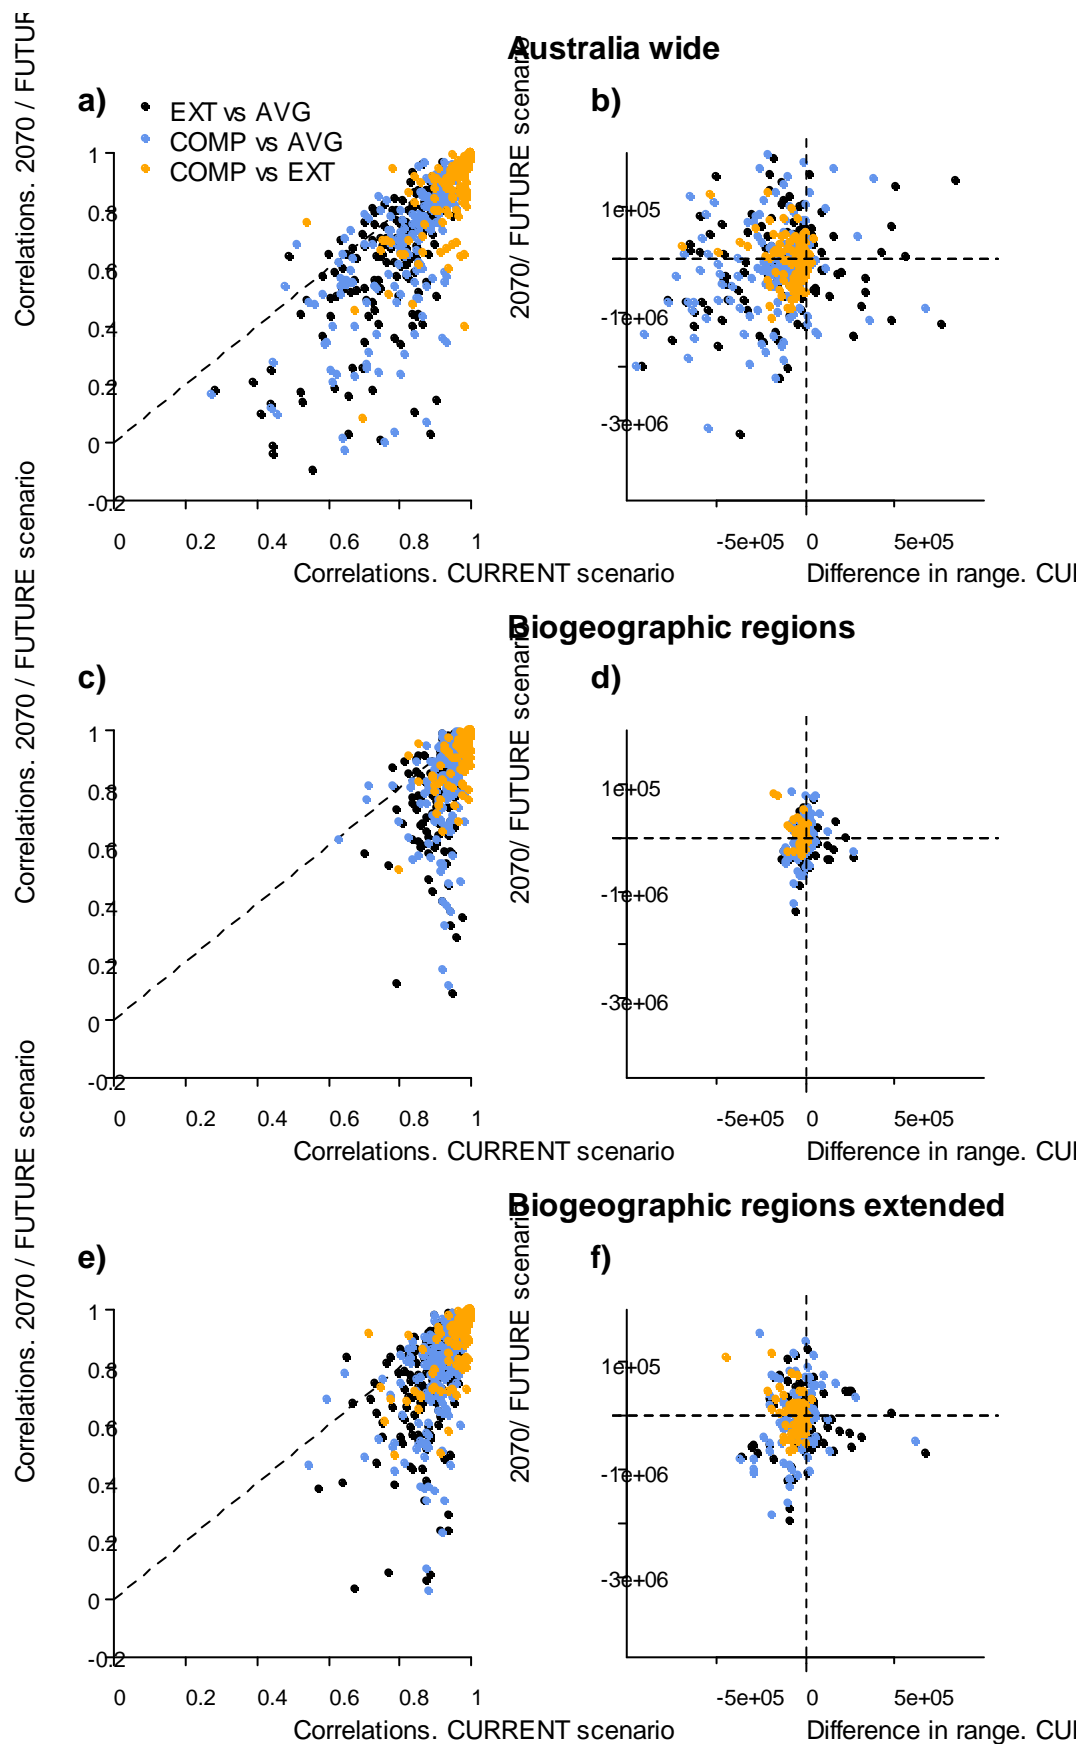

Figure A6

**Appendix 7. Habitat suitability and limiting factors' maps.**

Habitat suitability maps for the 13 species which showed the largest change in Pearson's correlations between current and future scenarios when comparing AVG and EXT models. Habitat suitability maps are detailed for each climate predictor set (rows: AVG, EXT and COMP). Predictive performance values (cross-validated AUC value, mean±sd) are indicated for the current predictions of each model. The figure shows the contrast between the predictions of each data set under current and future (2070) climatic scenarios (maps on first and second columns, respectively). The limiting factors maps (third column) show the variable that it is limiting the most an increase in habitat suitability at each grill cell and across the study area under the 2070 scenario and for each climate predictor-set individually (AVG, EXT and COMP). Refer to Table 1 for meaning of the variables' abbreviations.

Appendix 8. Multivariate Environmental Similarity Surfaces (MESS maps).

The multivariate environmental similarity surfaces indicate where extrapolation beyond the environmental values of the training data occurs. Warmer colours indicate extrapolation is occurring (darker reds being the most extreme) and therefore, predictions in these areas should be interpreted with extreme care. White and blue colours indicate areas where values of environmental conditions (climatic conditions in this case) are within the range of values of the training data set.

Current climate	Future hot and dry climate (2070 ACCESS 1.3 scenario)

**Appendix 9. Variation in predictions as a function of species traits**

Figure A9.1. Differences in predicted area between AVG and EXT model sets depending on the primary climate zone where species occur. Two climatic classifications schemes are considered: **a)** vegetation (Köppen) and **b)** temperature/humidity, both sourced from the Australian Bureau of Meteorology. The Köppen classification divides Australia in six major climatic zones: Ecuatorial, Tropical, SubTropical, Desert, Grassland and Temperate areas. The second climatic classification identifies six climatic zones based on different temperature and humidity combinations: hot-humid summer, warm-humid summer, hot-dry summer and mild winter, hot-dry summer and cold winter, warm summer and cold winter, and mild/warm summer and cold winter. We assumed a species occurs within a given climate zone only if 20% or more of its presence records fall within one of the climate zones identified by each classification scheme (i.e. each species can be counted in more than one climate zone). The number of species that fulfil this condition within each of the climate zones is indicated at the bottom of the plot. Differences are shown for current predictions (CUR, light grey boxes) and the future 2070 RCP 8.5 ACCESS 1.3 emissions scenario (FUT, dark grey boxes).

Figure A9.2. Pearson's correlations between the environmental suitability maps of models fit on the three predictor-sets (Y-axis) across species traits values (X-axis), under current climatic/weather conditions (solid circles) and under a hot and dry climate future scenario for 2070 (2070 scenario – 'crosses'). Each pair of predictor sets is represented with a different colour (EXT vs AVG – black- , COMP vs AVG – blue- and COMP vs EXT - orange). Body mass and activity cycle data were sourced from the mammals database PanTHERIA (Jones et al. 2009). We used the Interim Biogeographic Regionalisation of Australia spatial layer (IBRA v 7), to identify the biogeographic sub-regions where there were occurrence records of each species (http://www.environment.gov.au/land/nrs/science/ibra). We used the number of bio-geographic sub-regions in which a species occur as a proxy of geographic breath of the species. The number of species with available data for each trait is indicated in italics at the right bottom corner of each plot.
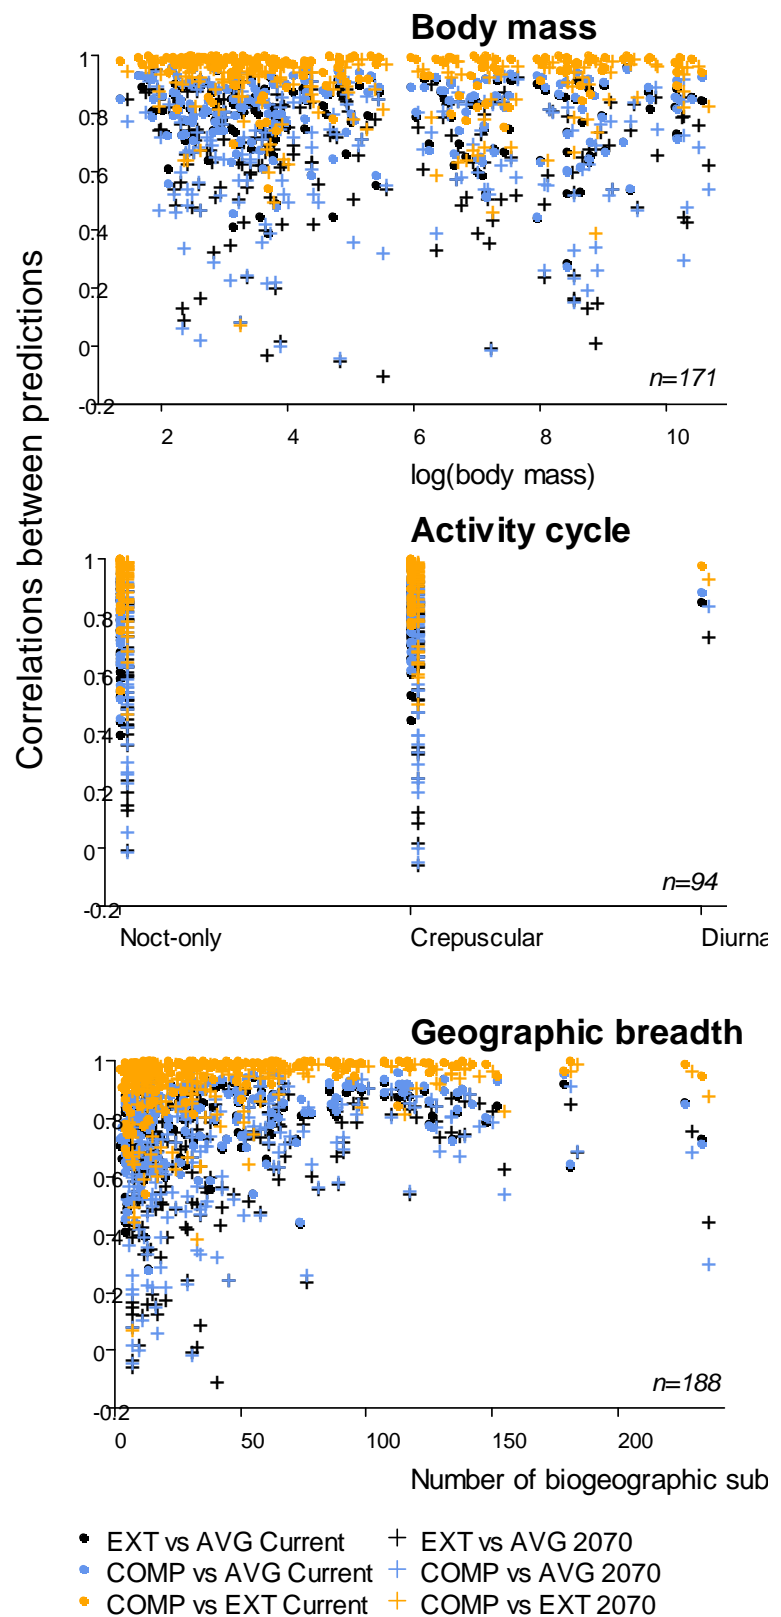

Figure A9.3. Range of changes in Pearson's correlations of environmental suitability maps between 2070 and current climates (Y-axis) across species traits values (X-axis). Each pair of predictor sets is represented with a different colour (EXT vs AVG – black- , COMP vs AVG – blue- and COMP vs EXT - orange). Body mass and activity cycle data were sourced from the mammals database PanTHERIA (Jones et al. 2009). We used the Interim Biogeographic Regionalisation of Australia spatial layer (IBRA v 7), to identify the biogeographic sub-regions where there were occurrence records of each species (http://www.environment.gov.au/land/nrs/science/ibra). We used the number of bio-geographic sub-regions in which a species occur as a proxy of geographic breath of the species. The number of species with available data for each trait is indicated in italics at the right top corner of each plot.
